1. Summary for Problem I

In this problem, we determine a strategy to divide a candidate's campaign finance resources in order to maximize his/her probability of winning the presidential election. In devising this plan, we consider the results from current polls indicating how well the candidate is doing compared to the opponent. The poll results include each person's certainty factors towards the candidates.

To approach this problem we follow this method: $money \rightarrow person \rightarrow state \rightarrow nation$. First, we model the relationship between the amount of money per citizen one candidate outspends the other candidate and the citizen's certainty factor towards the candidate who invests more money. The model is based on the arctan curve. We use data from the 2012 presidential election to determine the parameters of this curve. We then randomly generate data sets of citizens' certainty factors in order to simulate models for each state. For all states, we calculate how much money one candidate has to outspend the other candidate in order to win the state election. We rank the states by efficiency of investing money to winning that state. In order to make an optimized financial plan for winning the election, we conclude that the candidate needs to maximize the Electoral College votes relative to money spent. We continue to add states into our simulation until reaching 270 votes in total, which are enough to win the national election.

After this process, we are able to give the candidate a list containing the name of states and the least amount of money the candidate should outspend the opponent for each state.

To test our model, we use data from the ongoing 2016 United States presidential election. Based on the level of support for Hillary Clinton in polls for the 51 states, we divide her financial resources such that she outspends the least amount of money to win the election.

2. Summary for Problem II

In problem 2, we design efficient ambulance routes for Manhattan so that hospitals can send their ambulances to car crash sites in the shortest time.

To achieve this, we first build a vertex figure modeling Manhattan, including major crossings being the vertices and roads being the edges. We also add hospitals that can operate emergency surgeries into our vertex figure shown as vertices.

We assign values to the edges, such that the values represent the time an ambulance needs to pass the road completely. By using Dijkstra's Algorithm, we find the closest hospital to each vertex and include the vertices within the area of which the closest hospital takes charge. In this way, we partition Manhattan into 8 areas in terms of the results (there are 8 emergency hospitals in Manhattan), and the hospital is responsible for reacting to car accidents happening in its area. We also considered the situations when the closest hospital runs out of ambulances. Finally, we made a static to show the car crash and hospital response in Manhattan.

3. Model for Problem I

3-i Introduction

The United States goes through a presidential election every four years, during which two candidates run for office in the national election. The 51 states in the United States have different number of votes: the number of votes a state has is determined by the state's population. People vote in state elections, and all the state's electoral votes go to the candidate who wins the state election. If a candidate wins over 270 out of the 538 electoral votes in the national election, this candidate becomes the president.

While there are many strategies candidates can use to gain support, their financial strategy is the most important one. The amount of money they invest in a state has a direct impact on their success in the state's election. In this problem, we are trying to find a strategy that gives the candidate an optimized plan to distribute his/her money to the states.

3-ii Assumptions and Justifications

- 1) We know current poll information. People who participated in the poll will eventually vote in the election.
- 2) If someone is swaying between candidate A and candidate B, we split the swaying factor into halves for both candidates. For instance, if a person has a certainty factor of 18% towards candidate A and a certainty factor of 22% towards candidate B, we assume that this person has a certainty factor of 48% towards candidate A and a certainty factor of 52 % towards candidate B. Thus, everyone has only two certainty factors, either tending to candidate A or candidate B.

3) All people's certainty factors for the candidates will be influenced by how much money one candidate outspends on them than the other one.

- 4) If a person has a 50% certainty factor towards candidate A and a 50% certainty factor towards candidate B, we just need to spend a little bit more money on this person than our opponent in order to win this person's vote. We assume this "a little more money" is infinitely small, which means that a 50% certainty factor would win this person's vote.
- 5) For the same reason, if 50% of people in a state have 50% certainty factors for our candidate, we assume that we win this state's votes.
- 6) According to the electoral process in the United States, if a candidate wins a state, all the state's electoral votes go to this candidate.

3-iii Symbols

m	Money for a person
M	Money for a state
С	A person's certainty factor towards candidate A (our candidate)
1-c	A person's certainty factor towards candidate B
k	Number of people's certainty factor data sets for the state
Е	Efficiency of money
N	Number of electoral votes a state has
P	Population of a state

Table 3-1: symbols used in Problem I

3-iv Building the Model

Since we assume that all people's certainty factors will be influenced by the amount of money one candidate outspends the other one (assumption 2), we use a function to model this positive correlation.

Since a person's certainty factor will be harder and harder to increase and has an asymptote at y = 100%, we model the relationship between money and certainty factor using a $\arctan q$ curve¹.

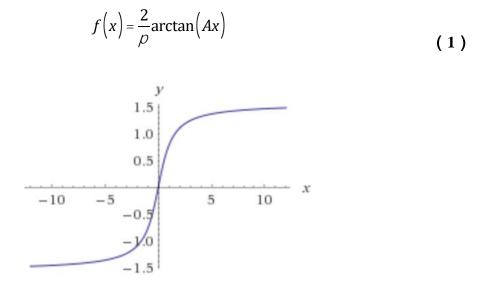

Figure 1. The curve of general arctan curve

We determine the constant A in (1) by using data from past presidential elections.

Precisely, we use data from the 2012 presidential election between Barack Obama and Willard Romney.

¹ http://www.wolframalpha.com/input/?i=y%EF%BC%9Darctan(x)

For the state of Florida which has a population of 18,801,310², we find that Romney outspent 998,973 dollars than Obama³, and Romney's supporting percentage in this state raised from 40% to 49%⁴. Since we divide the swaying factor in half, Romney's supporting rate in Florida actually raised from 48.5% to 49.5%.

We solve for A:

$$f^{-1}(49.5\%) - f^{-1}(48.5\%) = \frac{998973}{18801310}$$
$$A = 0.005161$$

Thus, we conclude that the relationship between money and a person's certainty factor towards one candidate can be model by⁵:

$$f(m) = \frac{2}{\rho} \arctan(0.005161 \ m)$$
 (2)

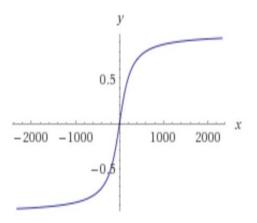

Figure 2. The curve of f(m)

² http://population2016.com/population-of-florida-in-2016.html

³ http://www.politico.com/story/2012/11/early-voting-results-2012-083176

⁴ http://elections.nbcnews.com/ns/politics/2012/all/president/#.WABloDJVaT8

⁵ http://www.wolframalpha.com/input/?i=y%3D2*arctan(0.005161*x)%2Fpi

However, people do not directly decide who the president shall be. They vote in state elections, and it is the state that has electoral votes in the national election. The number of votes each state gets depends on its population. Thus, we generate people's certainty factor datasets for each state, according to the state's population. To simplify the problem, we generate $\left[\frac{P_{state}}{100000}\right]$

datasets for the state's population, P_{state} , and times 100,000 in the end while calculating the campaign money to spend on this state. The table of states' populations and the number of electoral votes they have is included in Appendix 1.

We randomly generate data of people's certainty factors--c--for our candidate.

In the assumption, we assume that if 50% of the people in a state have 50% certainty factors for our candidate, then we win the state. Thus, our goal here is to find the least amount of money we need to outspend our opponent on a state so that we can have 50% of the people in the state having 50% certainty factors for our candidate.

For example, if a state has 6 sets of data for people's certainty factors- c_1 , c_2 , c_3 , c_4 , c_5 , c_6 in descending order--then our function would be like:

$$M = \min \mathop{\tilde{a}}_{i-1}^{3} \left(f^{-1} \left(50\% \right) - f^{-1} \left(c_{i} \right) \right)$$
 (3)

This will give us the amount of money we need to outspend the other candidate for this state to win this state. A positive M means that we need to outspend the other candidate in this state, while a negative M means that our opponent has to outspend us to a certain amount but still not able to win this state.

We do the same process for all 51 states. We also take into account the fact that the 51 states have different numbers of electoral votes. We want to minimize our spending while getting over 270 votes to win the election. When determining which states invest money in, we consider the efficiency of our money:

$$E_{state} = \frac{M_{state}}{N_{state}} \tag{4}$$

The smaller the E_{states} is, the less we need to spend on a state to get one electoral vote from the state. We spend campaign money on states with smaller E_{states} , till we are able to get over 270 votes.

Thus, we are able to have a plan of spending the least money while having our candidate win over 270 votes (code for realizing this model is in Appendix 2).

3-v Results from the Model

The result from our model is that, based on the data sets we generate, we need to outspend 96717 dollars than our opponent in order to win the election. This breaks down to each state:

Efficient State	State	Electoral votes	Money
4		20	1067
1	Texas	38	-1865
2	New York	29	-831
3	California	55	-1502
4	Florida	29	1866

5	Illinois	20	4418
6	Pennsylvania	20	8276
7	Ohio	18	10766
8	Michigan	16	14030
9	Georgia	16	17828
10	North Carolina	15	20429
11	New Jersey	14	23303

Table 2-2: Results table for which states to invest money in and how much to outspend

Among all the states, these 11 states are the ones with the smallest E_{state} s while giving us over 270 electoral votes to win the election. The full result table is included in Appendix 3.

3-vi Sensitivity Analysis

People's certainty factors are the only variables that affect our result.

3-vii Testing the Model

To test our model, we use data from the ongoing 2016 U.S. presidential election between Donald Trump and Hillary Clinton. We record Hillary Clinton's supporting percentages in each state, and view them as the average people's certainty factor towards her in these states (table of Hillary's supporting percentages in each state is included in Appendix 4)⁶. By putting these

 $^{^6\} http://www.upi.com/Top_News/US/2016/10/03/UPICV oter-state-polls-Donald-Trump-gains-support-in-all-but-5-states/6881475512049/$

certainty factors into our model, we get the optimized plan for distributing Hillary's finance resources.

Our result is that Hillary Clinton needs to outspend -89,523,541 dollars than Donald Trump to win the election. This breaks down into states:

State	Outspend trump
Washington D.C.	-36928082
Vermont	-8193297
Hawaii	-10735863
Rhode Island	-4577022
Delaware	-2741457
Maine	-2394096
Maryland	-5281931
Massachusetts	-3970813
Connecticut	-2325359
New Jersey	-3601180
New York	-4809224
Illinois	-2256864
Washington	-1257350
California	-4654121
Oregon	-122128
Michigan	121363
New Mexico	60776
Wisconsin	241970
Minnesota	361831
	Washington D.C. Vermont Hawaii Rhode Island Delaware Maine Maryland Massachusetts Connecticut New Jersey New York Illinois Washington California Oregon Michigan New Mexico Wisconsin

20	Florida	2130814
21	Ohio	1408491

Table 2-3: Results table for which states to spend money on and how much to spend for Hillary

These states will give Hillary 275 votes, which is enough to win the election. The result table of all the states is included in Appendix 5.

3-viii Strength and Weakness

In this problem, we are devising a strategy that gives the candidate an optimized plan to distribute his/her money to the states. Using our model, we are able to determine which states our candidate should invest in, and how much he/she should outspend the other candidate in these states.

Strength:

1) Our model is not just based on what our candidate should do: it's based on how much more our candidate should do than the other candidate. Comparing to models that give fixed amounts of campaign money to the states, our model is more suitable to the competitive environment of the election.

Weaknesses:

1) Our f(m) model is not based on a lot of research. Although we use data to test the parameters of the equation, a more advanced model is needed to model the complex relationship between money and people's certainty factors.

4. Model for Problem II

4-i Introduction

When a major car collision occurs, it is the hospitals' responsibility to dispatch ambulances to reach the site as soon as possible. However, in cities with heavy traffic and high frequency of collision cases, like Manhattan, it is necessary to design optimized ambulance routes so that the hospitals can accomplish the task of reaching crashing sites efficiently. In this problem, we are asked to develop such a plan for Manhattan.

4-ii Assumptions and Justifications

- 1) Ambulances come out of hospitals in Manhattan that have abilities to operate emergency surgeries, and go back to the same hospitals.
- 2) Because ambulance dispatch is not necessary if no people are hurt in the car accident, we do not consider the collision where no harm occurred.
- 3) To simplify the problem, we ignore the fact that roads in Manhattan are one-way roads. We assume that ambulances can go both ways.
- 4) We assume that every data point provided by the problem has an equal chance of having a car collision.
- 5) To simplify the problem, we assume that the ambulance only needs to get to the crossing near the actual collision site.

#841

4-iii Symbols

d	Road length
t	Time to cover the road, in seconds
P_{i}	The probability of a car crash occurring around a point
N_{i}	The number of actual car collision happened around that point
T	Duration of time in the record, in minutes

Table 4-1: Symbols used in Problem II

4-iv Building the Model

Firstly, we utilize the car accident data provided by the problem. Since we only send out ambulances when someone is injured or dead, we delete accidents that do not include any injuries or deaths.

We generate a vertex figure based on the map of Manhattan, with major crossings being the vertices and the roads being the edges. We also search for hospitals in Manhattan that can perform emergency surgeries, and find 8 hospitals in total (hospitals' names and locations are included in Appendix 6). We add them onto the vertex figure as vertices.

Figure 3. Vertex Figure based on the Map of Manhattan

We also assign values to the edges of the graph such that the values reflect the time an ambulance needs to pass this road completely. Based on the research, we find out that the ambulance speed limit in Manhattan is 25 mph⁷. Thus we assign values of t to the edges (value table is in Appendix 7):

$$t_{road} = \frac{d_{road}}{25 \ mph} \tag{7}$$

 $^{^7\} http://www.nytimes.com/2014/11/08/nyregion/a-lower-speed-limit-takes-effect-in-the-city-lower-speed-maybe-not-much.html$

For each vertex representing the crossing, we determine the closest hospital (spending the least time to get to) to that vertex using Dijkstra's Algorithm. Then we include the crossings into the range of the closest hospital found by the Algorithm. Since 8 hospitals are under our consideration, there are 8 areas partitioning Manhattan, which correspond to the 8 hospitals mentioned in Appendix 6.

Figure 4. Partitioned map of Manhattan

According to this map, the hospitals should respond to and only to car collisions inside their assigned range.

In addition, Dijkstra's Algorithm gives us the shortest routes that the ambulances should take from the hospital to the crossing. For example, if a car crash happens at vertex 210, our model will tell us to drive in the following route: $318 \Rightarrow 155 \Rightarrow 154 \Rightarrow 172 \Rightarrow 187 \Rightarrow 202 \Rightarrow 210$, which takes 119 seconds on the road to reach the crashing site and back.

In the assumption, we assume that every data point provided by the problem has an equal chance of having a car crash. We assign values to each vertex on the vertex figure, such that the value represents the probability of a car collision occurring near this vertex. We calculate this probability by dividing the actual number of car collisions happened in a zip code area over the duration of time T, which, in terms of the data provided by the problem, is:

$$T = 1550 days \ 24^{hours}/_{day} \ 60^{min}/_{hour} = 2232000 min$$
 (5)

Then, we are able to get the possibility, P_i , of a car crash happening near a vertex:

$$P_{i} = \frac{N_{i}}{T} \tag{6}$$

To simplify the problem, we separate Manhattan into $19^{\circ}19$ areas of equal sizes, in terms of its longitude and latitude. The data points i all fall on the areas, and we calculate the amount of car crash N_i in each area. We assign vertices values of P_i according to the area the vertices belong to. The results are shown in Appendix 10. Thus, with the output of a probability

distribution, we build a static model, which simulates the car crashes and hospital responses in Manhattan (Appendix 11).

Here are our results:

246th minutes

280 car accidents

321 ambulances sent by all the hospitals

286th minutes

262 car accidents

321 ambulances sent by all the hospitals

909th minutes

299 car accidents

321 ambulances sent by all the hospitals

We also consider the case when the hospital in the petitioned area where the ambulances are running out. According to Poisson Distribution,

$$P(k) = \frac{f^k e^{-f}}{k!} \tag{7}$$

the expected value of n car crashes happening at the same time can be calculated as the following:

$$E\left(\prod_{a=0}^{n}\left(X-a\right)\right)=I^{n}$$
(8)

If the number of car crashes happening in an area exceeds the number of ambulances provided by a certain hospital, we will compare the time that the ambulance spends from the

crashing site to the other crashing site (including dropping the patient to the hospital during the process) with the one that the ambulance spends from another hospital in Manhattan to the site.

4-v Results from the Model

In this problem, we are asked to design sufficient ambulance routes for Manhattan hospitals. Our result is the partitioned map of Manhattan and the static model. When a car collision happens, the hospital in the range area should be responsible for sending an ambulance to the site. Also, for most of the vertices, it is faster for the hospital in the area to dispatch an ambulance when available.

4-vi Sensitivity Analysis

For our model, the result can be affected by the following factors:

- 1) Traffic jam in Manhattan. Traffic jam is uncontrollable and is always changing, and it will affect the actual time an ambulance needs to reach the crashing site as well as the shortest route the ambulance can take.
- 2) The probability of a car crash happening. If the probability is timed by a constant c, which gives us c/ as the probability, then the expected value of n car crashes occurring at the same time can be calculated as $E\left(\prod_{a=0}^{n} (X-a)\right) = (c/)^n$. We can see that the probability is multiplied by c^n .

4-vii Strength and Weakness

Strengths:

1) Our model allows every point in Manhattan to be covered—wherever a collision happened, we have a plan.

2) We take into consideration that in a crowded city like Manhattan, traffic jam could be a big factor in influencing the traveling time on the roads.

Weaknesses:

- We do not consider every road in Manhattan in our model, and we do not consider the fact that most roads in Manhattan are one-way roads. Both can influence the shortest route an ambulance can take.
- 2) When we consider the concentration of car crashes, we simplify the problem by separating Manhattan into 19 '19 areas of equal size, which can cause some inaccuracy.

Appendix 6: Names of hospitals and their locations

Name	Address
Lenox Hill Hospital EMS	100 East 77th Street, New York, NY, 10021
New York Presbyterian Hospital EMS	525 East 68th Street, New York, NY, 10021
St. Luke's / Roosevelt Hospital Center EMS	1000 Tenth Avenue, New York, NY, 10019
Bellevue Hospital Center	462 First Avenue, New York, NY,
Metropolitan Hospital Center	1901 1st Avenue, Manhattan
Mount Sinai Beth Israel	First Avenue at 16th Street 10003
N.Y.U. Langone Medical Center	550 First Avenue, Manhattan
NewYork-Presbyterian/Lower Manhattan	170 William Street, Manhattan
Hospital
